Introduction to the manual of dielectric values

The relative dielectric constant (the dk-value) of liquids and bulk solid materials can – next to other influencing factors – be decisive when selecting a suitable technology for level measurement: This is where competent advice is required, but what distinguishes a competent partner? It is competence in product development, experience in the application, correct consultation and reliable service which distinguishes a reliable partner for process control technology.

In this booklet, Endress+Hauser endeavours to provide you with a listing of important substances which are commonly used in industry. We realise of course that such a listing is never complete in its scope. If you have the measured dielectric constant value for a product which is not in the book, we ask that you send us this value (the address can be found under the impressum). This will enable us to update the information in the next edition.

The reader can look for his product in two ways – either by looking for the trade name or the nomenclature (IUPAC). The dielectric constant values are listed with two separate measurement frequencies: at 1 MHz and at 100 kHz. Please understand the values in the book as standard values for individual measuring processes, as these are not absolute values. Should you find the measured value for your product at another frequency then this frequency can be considered the standard value. The next pages list the following measuring principles: "capacitive level measurement" and "Time Of Flight principles". The dielectric constant is important for the correct functioning in these measurements.

The publisher

Dielectric characteristics

The dielectric constant ϵ

The dielectric constant of an insulating material is the result of the dielectric number ϵ_r and the dielectric constant ϵ_0 in a vacuum.

$$\epsilon = \epsilon_r * \epsilon_0$$

$$\epsilon_0 = 0,08854 \text{ pF/cm} = 8,85419 * 10^{-12} \text{ F/m}$$

The dielectric number ϵ_r

The dielectric number of an insulating material is the relationship of the capacitance C_x of a capacitor where the area between the electrodes is completely and exclusively filled with the insulating material and the capacitance C_0 of the electrode alignment in a vacuum.

The following formula applies:

$$\epsilon_r = C_x / C_0$$

The dielectric number is a measure for the polarisation power of an insulating material.

Measuring principle

The dielectric characteristics are usually determined by a change in capacitance using special capacitors, whereby the different materials to be investigated are used as dielectricum.

The test body is aligned as dielectricum between two electrodes fitted closely to the surface of the material. The dielectric number is calculated on hand of the measured capacitance within the electrode alignment and its geometric dimensions.

Level measurement with capacitive probes

The capacitive measuring principle works on the basis of a capacitor. An alternating current produces an electrical field between two electrodes. The characteristic value of a capacitor is its capacitance C (pF), which again is determined by diverse factors:

- distance of the electrodes (s)
- area of the electrode surface (A)
- dielectricum, of the material between the electrodes

For the measurement of levels, this capacitor is formed from the conducting container wall and the capacitive probe in the container which is used in the measurement. If this probe is built into the container then the distance of the electrodes as well as the area of the electrode surface is fixed and there is no change. The capacitance is in that case dependent only on the characteristics of the material in the container.

$$C = \frac{2\pi \cdot \epsilon_0 \cdot \epsilon_r \cdot 2}{\ln(D/d)}$$

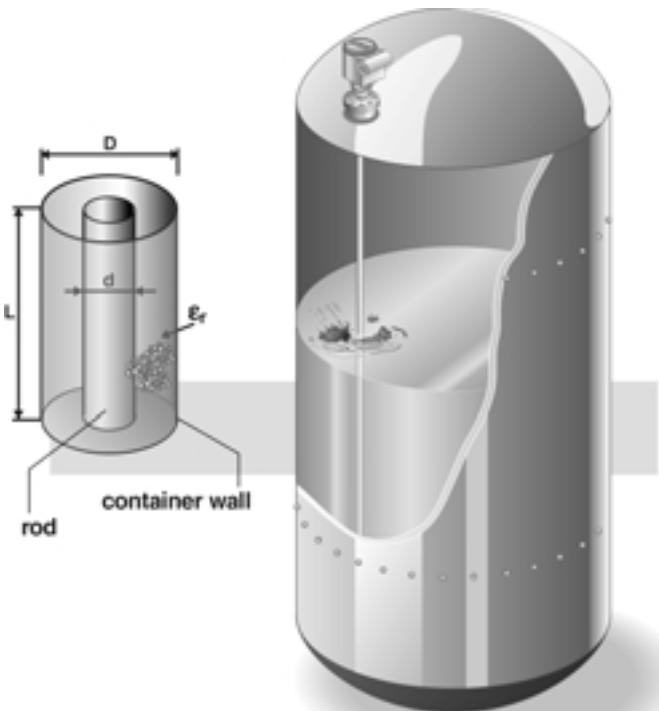

The ϵ_0 (electric field constant) is a natural constant.

$$\epsilon_0 = 8,854 \text{ pF / m}$$

The relative dielectric constant ϵ_r (shortened to dk in measurement technology), is a characteristic material constant suitable for every material and describes the relationship of how much the capacitance of a capacitor changes when filled with a certain material in relationship to a capacitor filled with air. ϵ_r is a number without dimensions. Air, per definition, has a ϵ_r of 1. The dielectric constant of liquids and solid materials is always more than 1. If for example, the air which is present between the probe and container wall is replaced by another material during the filling operation, the capacitance always increases.

In order to ensure that a change of capacitance in the probe is produced in sufficient magnitude for the electronics to respond, the dielectric constant of the product to be measured must be sufficiently large. With dielectric constants larger than 2 the application is usually uncritical and easy to handle. Measuring products with dielectric constants smaller than 2, sufficiently large changes of capacitance must be achieved with for example, the use of grounding pipes (increase in the sensitivity of the probe by reducing the distance of the plates) or a suitably large probe.

Occasionally, another measuring principle may have to be used. The dielectric constant however does not affect the measurement with conducting materials. In these cases a sufficiently large change in capacitance is always given.

$$C = \frac{2\pi \epsilon_0 \epsilon_r L}{\ln D/d}$$

Level measurement with microwaves

Light is the best known wave in the electromagnetic spectrum; everyone is confronted with it every day. Microwaves are waves produced electrotechnically within a defined frequency range. The microwave level measuring instrument from Endress+Hauser for example transmits with a frequency of app. 6 GHz and app. 26 GHz. Level measurement uses microwave technology to detect material surfaces.

The physical characteristics of microwaves are unique. Microwaves are practically not influenced by diverse gases. They function practically problem-free in a vacuum, they are negligibly influenced by high temperatures and pressures, build-up and condensate. These characteristics make microwave technology one of the most universal in comparison with other measuring principles.

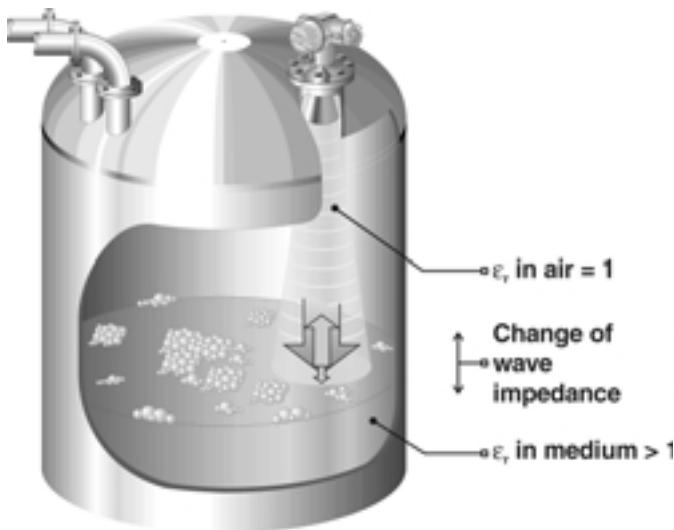

The microwave principle

Basically, the microwave principle is a tracking system working with very short, electromagnetic waves.

This principle is also called Radar measurement. Radar information is transmitted and gathered over a channel consisting of a transmitter, transmitter antenna, target, receiving antenna and receiver. The transmitter is a source of high frequency output which is radiated in bundled form. Only a portion of this output reaches the radar receiver. Reflection may be diffuse or complete, depending on the geometry, structural and material characteristics.

The microwave measurement process is a time of flight process, i. e. the measuring instrument determines the running time of the microwaves and changes it into a level proportional 0/4...20 mA signal.

Microwave measurement in an unobstructed tank works as of a DK value of 2. Measurement in a pipe (bypass/surge pipe) requires a DK value as of c. 1.4.

Level measurement with micro-impulses

As of 1998, Endress+Hauser offers measuring instruments operating on the time of flight principle (micro-impulses), on the world markets. The typical applications here are finely grained bulk materials up to max. 20 mm granulation size, having a minimum dielectric value of 1.8. This includes e. g. lime, cement, gravel, grains, sugar, coal, and fly ash.

The micro-impulse principle

Very short impulses with a high repetitive frequency (460 kHz) are irradiated from the surface of a probe. The impulses may be visualised as energy packages with a diameter of c. 30 cm, running along the probe with the speed of light. As the environment around the probe changes with the presence of bulk materials, the electrical impedance also changes. This results in a partial reflection of the impulse, measured by a high frequency sampler after reception.

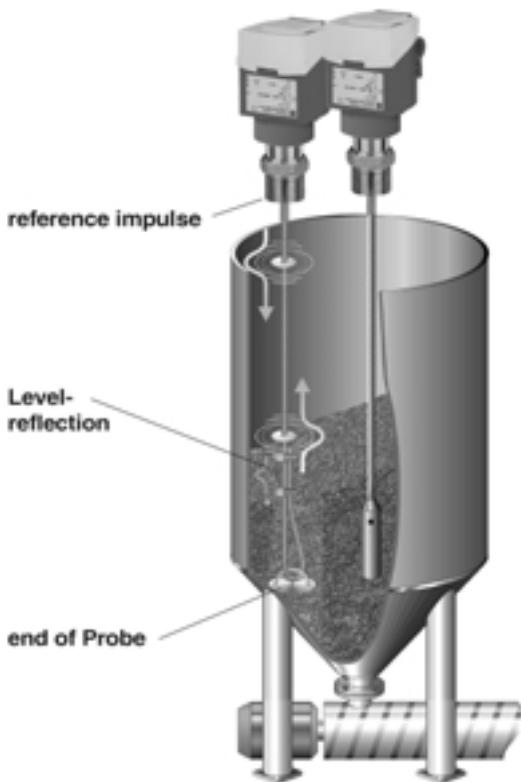

The time between the transmitted and the reflected impulse is the measure for the distance between the process connection (flange or thread) and the level of the material. As the rise time of the pulse is extremely short, the emitted frequency band is very wide; the "Time domain reflectory (tdr)" is used for signal recognition. With this method, a $\pm 1\%$ tolerance in measurement (over the entire range) is guaranteed. The micro-impulse process reliably recognises solids as of a DK value of 1.8.

$$D = c \cdot \frac{\Delta t}{2}$$

D = distance

c = speed of light

t = time-of-flight difference
between
the time of transmitting
and receiving
